ABSTRACT

The paper proposes a novel algorithm called *AtomRace* for a dynamic detection of data races. Data races are detected as a special case of atomicity violations on atomic sections specially defined to span just particular read/write instructions and the transfer of control to and from them. A key ingredient allowing AtomRace to efficiently detect races on such short atomic sections is a use of techniques for a careful injection of noise into the scheduling of the monitored programs. The approach is very simple, fully automated, avoids false alarms, and allows for a lower overhead and better scalability than many other existing dynamic data race detection algorithms. We illustrate these facts by a set of experiments with a prototype implementation of AtomRace. Moreover, we also show that AtomRace can be easily extended to not only detect races, but also to automatically heal them. Further, AtomRace can also be applied to detect atomicity violations on more general atomic sections than those used for the data race detection. They can be defined by the user or obtained by some static analysis.

1. INTRODUCTION

Concurrent, or multi-threaded, programming has become popular. New technologies such as multi-core processors have become widely available and cheap enough to be used even in common computers. Thus, true concurrency moves from computing centres to everyday life. However, as concurrent programming is far more demanding, its increased use leads to a significantly increased number of bugs that appear in commercial software due to errors in synchronization of its concurrent threads. This stimulates a more intensive research in the field of detecting and removing of such bugs.

This article proposes an architecture for detecting and on-the-fly healing of data races and atomicity violations in Java. The architecture is based on a novel algorithm, which we call *AtomRace*. AtomRace detects only true bugs and does not produce false alarms—at least in the case of *data races*. In the case of *atomicity* problems, the same result is achieved if the algorithm is provided with a correct definition of atomic sections of the code. If they are not provided, they can be approximated either via static or dynamic analysis, of course, with a certain loss of precision. The algorithm scales well and produces only a moderate overhead which allows it to be used not only during testing but also in the field.

The article is organized as follows. The rest of this section contains a short overview of state of the art in data race and atomicity violation detection and healing followed by a short introduction of our approach. Section 2 describes the proposed architecture, including the way how the AtomRace algorithm is incorporated into a self-healing machinery. The AtomRace detection algorithm is introduced in Section 3, followed by a description of the static analysis used for obtaining the correct atomicity sections of the application. Healing capabilities of the AtomRace extensions are discussed in Section 5. Finally, a few experiments document the main outcomes of our solution.

1.1 Data Race and Atomicity Detection and Healing Techniques

Verification problems for programs written in general programming languages are usually undecidable, which is, of course, the case of race detection too. Therefore, tools for data race and atomicity violation detection are based on detecting data races dynamically when only one execution trace is analyzed, or statically, using various approximative and/or semi-algoritmic solutions. Up to now, many different approaches of this form have been proposed. Below, we briefly summarise some of them.

Most current dynamic analysis tools are based on tracking the so-called *locksets* using the observation that if every shared variable is protected by a lock, there is no possibility of operations on this variable being simultaneous, and therefore a race is not possible. A popular such algorithm is *Eraser* [25], later improved with an ownership model [30]. However, a problem of lockset-based algorithms is a high

number of false alarms when other than a lock-based synchronization is used. One way how to reduce the number of false alarms is to use the Lamport's *happens-before* relation [14]. A combination of the happens-before relation with the lockset-based approach is, e.g., used in [3, 21, 6, 32, 13]. The works [21] and [32] are based on using the so-called *vector clocks* [17] monitoring the happens-before relation. Probably, the most advanced algorithm combining the happens-before relation with locksets is the *Goldilocks* algorithm [6], which not only shrinks the so-far computed locksets while monitoring an evolving run of a program, but also allows them to grow.

Some further works are then motivated by the fact that data race freedom does not imply correct synchronization. A concept of *high-level data races* has been described in [1], together with a method of detecting them using the so-called *view consistency*. In [29], a principle of *method consistency* extends the view consistency to accommodate the scope of methods as a consistency criterion. In [9], a similar notion of *method atomicity* is studied. As the granularity on the level of methods may be too coarse, yet other approaches have then been proposed based on the principle of *serializability* [31, 16, 28], which exploits the idea that two consecutive accesses from one thread to a shared variable should not be interleaved with an unserializable access from another thread. In particular, the AVIO tool [16] introduces a notion of *access interleaving invariants* (AI invariants) identifying a number of patterns how concurrent threads can access a shared variable, which are then classified according to their possible undesirable effects.

On the other hand, numerous static analyses have been introduced to detect data races and atomicity violations. To infer violations in the synchronization, they use, e.g., primarily flow insensitive *type-based systems* [8, 23, 24] or mostly flow sensitive *static versions of lockset algorithms* [7, 19, 12]. Further, there also exist works for detecting data races using specialised *model checking* techniques—cf., e.g., [10, 5].

All the previous work focused only on detecting data races and atomicity violation. We have focused in our previous work also on healing them on-the-fly [13]. ToleRace [18] also tries to detect and remove the detected races from the application by duplicating of shared data inside a critical section and so provides an illusion of atomicity when the shared data is updated. If a conflict among copies occurs, ToleRace can in some cases solve it and so hide or tolerate the problem.

1.2 The AtomRace Approach

AtomRace is a new dynamic data race and atomicity violation detection algorithm. As for detecting data races, it is based *directly* on the definition of a (low-level) data race which says that a data race occurs if two or more threads access a shared variable and at least one access is for writing and there is no explicit synchronization which prevent these accesses from being simultaneous. Thus, a data race can be detected by finding a situation when such an access scenario occurs. In AtomRace, this is detected as a special case of an *atomicity violation* when atomic sections are defined simply as sequences of instructions $BeforeAccessEvent$, i, $AfterAccessEvent$ where i is a read or write instruction on shared data and $BeforeAccessEvent/AfterAccessEvent$ are special instructions that are added by instrumentation before/after i. Of course, a data race happens only when at least one of two colliding atomic sections is based on a write instruction. The probability of spotting a collision of this kind in a regular program is low, however, we exploit *noise injection* techniques [27, 4] that may significantly increase this probability—which is actually proven to be the case by our experiments. Note that this mechanism of detecting data races does not generate false alarms.

Further, the atomic sections monitored by AtomRace may be extended to span more subsequent instructions on a shared variable to detect not only data races but other kinds of problems in synchronization. Such sequences may be obtained from the AI invariants, may be predefined by the user, or obtained by some static analyses directed by looking for standard patterns of code sections to be performed atomically (e.g., testing a shared variable to be non-null and sub-sequently dereferencing it, etc.).

Unlike many other approaches, AtomRace does not dependend on the kind of synchronization primitives used in the analysed program. It naturally supports all types of synchronization (including user defined synchronization primitives) because it does exploit the semantics of such mechanisms, but directly checks the correctness of a program execution. AtomRace can be used not only for detecting synchronization problems, but we also extend it to heal the detected problems either by adding synchronization or influencing the Java virtual machine scheduler [13]. Additional advantage of AtomRace is a low overhead introduced to the monitored application and the fact that it does not generate false alarms when detecting data races. The number of false alarms produced by AtomRace during more general atomicity violation detection depends on the correctness of the predefined atomic sections.

2. ARCHITECTURE

The proposed architecture is depicted in Figure 2 and consists of three modules. The *execution monitoring* module watches the program and triggers predefined events occurred during the execution. Additional information describing the event are collected and the event is then passed to the analysis engine. The *analysis engine* uses AtomRace algorithm to decide if a problem occurs. Finally, the *healing logic* can influence the behavior of the program to prevent the problem manifestation. In the following, we look at the modules in more detail.

Execution monitoring must provide the analysis engine with the following information about each event: (1) the thread which the event belongs to, (2) the shared variable (if any) that was accessed within the event, (3) type of the event determined by the executed instruction, and (4) localization of the event in the application code. For each access of shared variable, two events are needed: *beforeAccessEvent* which is invoked right before the access instruction and *afterAccessEvent* which is invoked right after the access instruction.

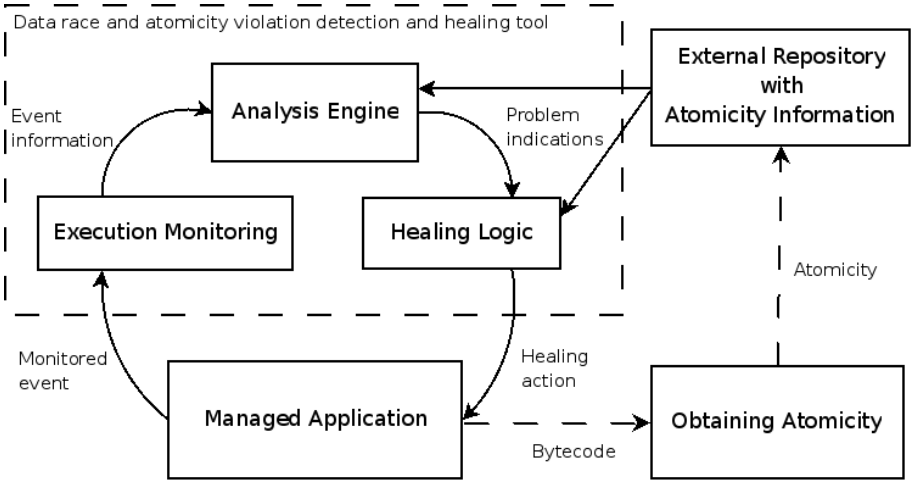

Figure 1: Architecture diagram

The **analysis engine** uses AtomRace algorithm to detect data races and atomicity violations in the stream of events provided by the monitoring module. In the case of atomicity violation detection, the correct atomicity is determined in advance and is available to AtomRace from the external repository. The detection algorithm and the way how to obtain correct atomicity in advance will be described later in Sections 3 and 4.

The **healing logic** module controls the influencing of the execution. It can be done by safe but not very efficient influencing of Java scheduler or by more effective but potentially dangerous adding a new synchronization lock. The healing has to follow the restriction given by correct atomicity to reach the goal. Again, the atomicity information is available in the external repository. The healing will be described in more detail in Section 5.

We expect the following practical usage of the AtomRace. At the end of the application development, the program is analyzed and the set of atomicities that should be followed is determined and stored to the external repository. The formal verification like static analysis or model checking is then used in order to check whether it is safe to enforce particular atomicities for the bug healing. For instance, one should check that enforcing the atomicity of a section of code by introducing an addition lock does not cause a deadlock. The atomicity repository is then distributed together with the application to the customer. In the field, the program is executed together with AtomRace which watches the execution and automatically heals detected bugs.

3. THE ATOMRACE ALGORITHM

AtomRace is an algorithm for detecting data races and atomicity violations at runtime. Data race detection in AtomRace is fully automated and self-contained. For atomicity violation detection, AtomRace expects the atomic sections that should be monitored to be given to it as a part of its input. As we discuss in Section 4, they can be manually defined by the user or obtained by some further static and/or dynamic analysis. In fact, data race detection is implemented in AtomRace as a special case of atomicity violation detection on atomic sections that are specifically defined for this purpose.

AtomRace does not track the use of any concrete synchronisation mechanisms—instead, it solely concentrates on the consequences of their absence or incorrect use. That is why AtomRace can deal with programs that use any kind of synchronisation, including non-standard synchronisation mechanisms defined just for the concrete case. AtomRace may miss data races or atomicity violations, but, on the other hand, it does not generate any false alarm in the case of data race detection nor in the case of atomicity violation detection (wrt. the atomic sections provided to it).

We expect AtomRace to work on Java bytecode[1] instrumented as follows: for each shared variable v (corresponding to a field of a certain class in Java) that is to be monitored, we assume each access to v at a location loc to be preceded by a code fragment that generates an event $beforeAccessEvent(v, loc)$ and to be followed by a code fragment that generates an event $afterAccessEvent(v, loc)$. We view the code fragments generating these events as an implementation of special pseudo-instructions denoted as $beforeAccess(v, loc)$ and $afterAccess(v, loc)$, and we allow atomic sections to span from/to such instructions. Moreover, we also allow the code to be instrumented to generate events $atomExitEvent(v, loc)$. As before, we view the code generating such events as an implementation of a special pseudo-instruction referred to as $atomExit(v, loc)$ in the following. This kind of events is used in special cases of the control flow (like exception handling) when it does not make sense to continue with checking the current atomic section.

[1]We refer to Java here, but the basic principles of the algorithm can be used in the context of other programming languages too. The only thing that is Java-specific is the treatment of the special cases discussed at the end of the section.

3.1 Data Race Detection

A data race is defined as a sequence of two accesses to the same shared variable from different threads provided that (1) these accesses are not separated by any synchronisation, and (2) at least one of them is a write access. In AtomRace, such a situation is detected by looking for a violation of *primitive atomic sections* of the form $beforeAccess(v, loc)$; $read/write(v)$; $afterAccess(v, loc)$ where $read/write(v)$ is any instruction reading or writing a shared variable v. It is clear that if such a primitive atomic section based on a read instruction is broken by a write instruction, or if a primitive atomic section based on a write instruction is broken by a read or write instruction, a data race happens because there is for sure no synchronisation used neither between $beforeAccess(v, loc)$ and $read/write(v)$ nor between $read/write(v)$ and $afterAccess(v, loc)$.[2] In order to significantly increase the probability of detecting data races via violating the described primitive atomic sections, which are very short, we use techniques of noise injection discussed in Section 3.3.

Data race detection based on the above idea can be implemented in a very simple way within handling the events generated by $beforeAccess(v, loc)$ and $afterAccess(v, loc)$ as we show in Figure 2. For each shared variable v, we define a variable $Access(v)$ which is `null` in the case v is not being currently accessed by any thread, and which contains a couple (t, loc) otherwise, where t is the thread that is accessing v at the location loc. In the latter case, to simplify the description, we use $Access(v).t$ and $Access(v).loc$ to refer to the thread and location stored in $Access(v)$, respectively. Given a location $loc \in Loc$, we use a function $getMode : Loc \rightarrow \{read, write\}$ to obtain the way v is accessed at loc. We use $t_{current}$ to refer to the currently executing thread.

Initialisation:
$\forall v \in SharedVariables : Access(v) =$ `null`;

Computation:
switch ($AtomRaceEvent$) {
case : beforeAccessEvent(v, loc)
  if ($Access(v) ==$ `null`) **then**
    $Access(v) = (t_{current}, loc)$;
  else
    if (($getMode(Access(v).loc) ==$ `write`) ||
      ($getMode(loc) ==$ `write`)) **then**
      RACE DETECTED

case : afterAccessEvent(v, loc)
  if ($Access(v).t == t_{current}$) **then**
    $Access(v) =$ `null`;
}

Figure 2: Data race detection in AtomRace

Let us, however, note that the Algorithm in Figure 2 is a little simplified. In reality, it has to be refined a bit to cope with some special situations that may arise in Java. First, variables defined as `volatile` [22] are intended for use in cases where data races are tolerable and so, they should not be monitored by the algorithm. Next, Java uses a special `<clinit>` method to assign implicit values to static variables when they are used for the first time. This initialisation requires a write access which should, however, not be taken into account when looking for data races. Finally, the algorithm should not track shared variables declared as `final` because their values cannot be changed during the execution.

Another feature of AtomRace that deserves a comment is its ability to give the user a very valuable *diagnostic information* in case a data race is detected. Namely, the user can be informed about the particular shared variable (i.e., in Java, about the class instance and the field name) on which a data race was detected and about the two program locations whose concurrent execution lead to the data race. Such a piece of information is also very useful within the self-healing process.

3.2 Atomicity Violation Detection

We now extend the above presented algorithm such that it allows us to deal with more general *atomic sections*. However, as above, we still assume an atomic section to be associated with a single shared variable only. For a shared variable v, we view an atomic section as a code fragment which is delimited by a single entry point and possibly several end points. The intended meaning of an atomic section over a variable v is that when a thread t starts executing within the atomic section, no other thread should access v before t reaches an end point of the atomic section (with the exception of some kinds of accesses that may be explicitly allowed for the given atomic section). Quite naturally, we assume the entry point of an atomic section to correspond to some $beforeAccess(v, loc)$ instruction and the end points to correspond to some $afterAccess(v, loc')$ or $atomExit(v, loc')$ instructions.

To allow a specification of which accesses from other threads *should not be considered to break an atomic section* when it is being executed by some tracked thread, we associate a (possibly empty) subset of the set $\{read, write\}$ with each end point of each atomic section. This subset indicates which kind of operations *can be* performed by other threads on v while a tracked thread is running between the entry point of a given atomic section and a given end point of this atomic section. As discussed in Section 4, we can use this information, e.g., to allow not only checking of pure atomicity, but to allow for handling not purely atomic, but *serializable accesses* (in the sense of [16]) as well.

When dealing with *several atomic sections* associated with the same variable v, we require that these sections *do not overlap* in any other way than possibly on their entry and end points. More precisely, the only allowed overlap is that one atomic section has an entry point $beforeAccess(v, loc)$ while the other has an end point $afterAccess(v, loc)$ for the same location loc. Due to this requirement, a process can only be in one atomic section at a time (with the exception of leaving one section and at the same time entering another).

[2] Intuitively, the primitive atomic sections are defined such that they start *after* the instruction preceding a given read/write instruction and stop *before* the instruction following it.

As shown in Figure 3, detection of atomicity violation can again be implemented in a simple way within handling the events $beforeAccessEvent(v, loc)$, $afterAccessEvent(v, loc)$, and $atomExitEvent(v, loc)$. For the purpose of describing the algorithm, we expect the set of atomic sections associated with a variable v that are supposed to be tracked and that satisfy the conditions described above to be encoded in a "flattened" way as a set $Atomic(v)$ of triples $(loc_{entry}, loc_{end}, A)$ where $A \subseteq \{read, write\}$ and loc_{entry}, loc_{end} are locations corresponding to entry and end points of particular branches of the atomic sections encoded by $Atomic(v)$. We use the notation $Atomic(v).A(loc_1, loc_2)$ to refer to the set A in $(loc_1, loc_2, A) \in Atomic(v)$.

For each shared variable v whose atomic sections we intend to monitor, we maintain the set $Access(v)$ used already in Figure 2. Moreover, we also build a set $SuspectAccess(v)$ which contains types of accesses to v that came from other threads than the one whose execution in an atomic section over v we are currently monitoring. The algorithm works in such a way that if a thread t is entering an atomic section over a variable v over which no atomic section is currently being monitored, we start monitoring accesses to v from other threads, and once t is leaving the atomic section via some end point, we check that no undesirable access to v from a thread other than t has happened. Note that we always monitor atomicity of an atomic section associated with a certain variable v just for a single thread—the one that entered a critical section over v while no other thread was currently executing an atomic section over v.

Initialisation:
$\forall v \in SharedVariables$:
  $Access(v) = \texttt{null}, SuspectAccess(v) = \emptyset$;

Computation:
switch ($AtomRaceEvent$) {
case : beforeAccessEvent(v, loc)
  if ($Access(v) == \texttt{null}$) **then**
    if ($\exists l_{end}, A : (loc, l_{end}, A) \in Atomic(v)$) **then**
      $Access(v) = (t_{current}, loc)$;
  else
    if ($Access(v).t$!= $t_{current}$) **then**
      add $(t_{current}, loc)$ **to** $SuspectAccess(v)$;

case : afterAccessEvent(v, loc), atomExitEvent(v, loc)
  if ($Access(v).t == t_{current}$ &&
    $\exists A : (Access(v).loc, loc, A) \in Atomic(v)$) **then**
    if ($SuspectAccess(v)$!= $\emptyset$) **then**
      $A = Atomic(v).A(Access(v).loc, loc)$;
      foreach $(t_s, l_s) \in SuspectAccess(v)$ **do**
        if ($getMode(l_s) \notin A$) **then**
          ATOMICITY VIOLATION DETECTED
    $Access(v) = \texttt{null}$;
    $SuspectAccess(v) = \emptyset$;
}

Figure 3: A simplified version of the AtomRace algorithm for detecting atomicity violation

Note that the algorithm shown in Figure 3 is a bit simplified wrt. the above described functionality. In particular, we have left out the treatment of overlapped atomic sections, which can, however, be added in a straightforward way into the code handling the $beforeAccessEvent(v, loc)$ and $afterAccessEvent(v, loc)$ events.

The algorithm can be easily extended to cope with *circular atomic sections*, i.e. atomic sections where $loc_{entry} = loc_{end} = loc$, but we do not want the atomic section to terminate just after firing the statement at the location loc. In such a case, we tag such a section in a special way, and the algorithm does not leave the atomic section during the first occurrence of $afterAccessEvent$ at loc.

Finally, the algorithm can also be extended to support recursive atomic sections by counting how many times the section has been entered and left and by terminating the atomic section only when these numbers are equal.

3.3 Race and Atomicity Violation Exhibition

The AtomRace algorithm was originally developed for detecting data races and atomicity violations for healing the problems at runtime. Therefore, the aims of the algorithm slightly differ from the previous approaches. The first difference is not to find as many potential problems as possible (with the chance of false alarms) but to report only true alarms in order to invoke the expensive healing mechanisms only when some problem really occurs. The next essential aim of the algorithm is to cause as small overhead as possible due to the intent to use it in the field. This is achieved by using less shared data structures than in many other race detection algorithms. Despite that, this algorithm can be also very useful in bug hunting within the application testing if suitable *noise injection* is used.

As we have already mentioned, the problem with using AtomRace to find as many data races and atomicity violations as possible is that the considered atomic sections may be very short and the probability of observing a real conflict on them may be very low. However, the probability may be significantly increased by suitably influencing the execution of the program what is exactly the purpose of noise injection. In general, noise injection is a technique that forces different legal interleavings for particular executions of a test in order to increase the concurrent coverage. In fact, it simulates the behaviour of various possible schedulers. The noise can be injected at any instrumented point (e.g., during the execution of $beforeAcces(v, loc)$ or $afterAccess(v, loc)$) of the tested software. When such a point is reached, the noise heuristics decides—randomly or based on a specific bug-finding technique—if it injects some kind of delay or other kind of influencing the execution (like a context switch) there or not.

The introduction of noise can help the detection of races and/or atomicity violations in two ways: firstly, different legal thread interleavings are enforced. Secondly, randomly chosen atomic sections are executed for a longer time period and therefore the probability that a conflict will occur on them is increased. Both of this helps to see conflicts that would not be seen otherwise. Of course, the probability of seeing a data race and/or atomicity violation can then be rapidly increased also if a true multiprocessor computer is used for testing.

In our prototype implementation of AtomRace, we use the ConTest infrastructure [4, 20, 27] for instrumentation, handling the generated events, as well as for noise injection. Based on our experience with ConTest and influencing the Java scheduler for self-healing purposes [13], we have proposed three noise heuristics for increasing the probability of detecting data races and/or atomicity violations. All of them are based on injecting calls of `Thread.sleep()` inside atomic sections to increase their duration followed by calls of `Thread.yield()` to force a thread switch. The probability of noise injection in the given location is driven by the parameter that ranges from 0 (=never) to 1000 (=every time). The duration of sleep is given by the number of milisecond that sleep should last. The three heuristics we have implemented are the following:

- *A random heuristics.* This is the simplest heuristics that can be used during a normal testing when there is no suspicion that something wrong is happening in the program. It injects noise to randomly chosen atomic sections.
- *A variable-based heuristics.* This heuristics can be used when some concrete variable is suspected to be accessed with a wrong synchronisation. The noise is injected to the sections associated with instances of the suspected variable only.
- *A heuristics based on program locations.* This approach allows the user to identify atomic sections which are suspected to be problematic. The noise is injected to the given program locations only.

The second and third heuristics can be also used for testing and debugging. If AtomRace detects a race or an atomicity violation in one run of the tested software, the developer can use a noise injection focused on the suspected variable or the problematic program locations to increase the probability of a repeated manifestation of the detected problem.

4. OBTAINING ATOMICITY

A correct identification of the atomic sections to be monitored is crucial for our detection and healing mechanisms to work properly. Such atomic sections can be defined either manually by the user or obtained automatically via static and/or dynamic analysis.

Below, we propose two concrete static analyses for deriving the atomic sections to be monitored. The so-called *pattern-based* static analysis looks for appearances of typical programming constructions that programmers usually expect to execute atomically. The second static analysis builds on the *access interleaving (AI) invariants with the serializability notion* from [16]. Moreover, we also discuss a possibility of using a subsequent dynamic analysis to identify candidates for atomic sections which are likely not to correspond to real atomic sections and that are thus to be dropped from the set of monitored atomic sections.

Before going into more detail of the mentioned static and dynamic analyses, let us note that like in the case of data races, it does not make sense to consider atomic section over `final` variables whose values do not change. Further, it is not needed to monitor atomic sections laying within the `<clinit>` method, which is guaranteed by the JVM to be executed atomically.

4.1 Pattern-based Static Analysis

Pattern-based static analysis identifies blocks of code that are likely to be intended to execute atomically based on looking for some typical programming constructions, for which such an assumption is usually done. Two examples of such patterns are the so-called load-and-store and test-and-use patterns [13].

The *load-and-store* pattern originates from an assignment statement that is translated into the bytecode as a sequence of instructions consisting of one or more load instructions on a shared variable v followed by one store instruction on the same variable (as, e.g., in the case of the `x++` statement). The atomic section covering this pattern starts at $beforeAccessEvent(v, loc_1)$ of the first load instruction on v and ends at $afterAccessEvent(v, loc_2)$ of the store instruction on v. This tuple of locations can safely be interleaved with read accesses on v, and hence the A set associated with loc_1 and loc_2 is $A = \{read\}$. To cover the possibility of an exception before the control reaches loc_2, we also allow the atomic section to end by an $atomExitEvent(v, loc_3)$ event where loc_3 corresponds to the nearest location of the appropriate exception handling branch. With this end point of the atomic section, we associate the set $A = \{read, write\}$ meaning that we do not check for atomicity on the exception handling branch.

The *test-and-use* pattern is a conditional statement where the condition is checked at the beginning of the statement and then the result is used inside the statement without making sure that the condition still holds (as, for instance, in the statement `if (x != null) { x.next = ... }`). Such a construction is translated into the bytecode as a sequence of instructions consisting of one load instruction on a shared variable, a branching instruction, and one or more further load instructions. The atomic section in this case starts at $beforeAccessEvent$ of the first load instruction and ends at the $afterAccessEvent$ of the last load instruction in the branch of the control flow graph (CFG) that is executed if the condition holds. Such an atomic section can be safely interleaved with read accesses, and so $A = \{read\}$. The other branch of the condition and all the exception branches have to be covered by using $atomExitEvent$ with $A = \{read, write\}$.

More similar patterns can, of course, be defined and used.

4.2 AI Invariant-based Static Analysis

Inspired by the notion of *AI invariants* [16], we may statically identify couples of two immediately consequent accesses to a shared variable v in the interprocedural CFG as candidates for atomic sections. A dynamic analysis (described later) can then be used to remove the candidate sections which do not correspond (or do not seem to correspond) to code sections that should really be executed atomically.

Interleaving scenario	Description
$read_{local}$ $write_{remote}$ $read_{local}$	The interleaving write makes the two reads have different views of the same memory locations.
$write_{local}$ $write_{remote}$ $read_{local}$	The local read does not get the local result it expects.
$write_{local}$ $read_{remote}$ $write_{local}$	Intermediate result that assumed to be invisible to other threads is read by a remote access.
$read_{local}$ $write_{remote}$ $write_{local}$	The local variable relies on a value from the preceding local read that is then overwritten by the remote write.

Table 1: Unserializable interleaving scenarios

Note that while building the atomic sections based on identifying couples of consecutive accesses to the same shared variable, we often obtain atomic sections with several different end points based on $afterAccessEvent$ due to the possible branching of the code. For each end point, we define the appropriate A set using the notion of *serializability* defined in [16] and listed in Table 1. In fact, Table 1 lists unserializable scenarios, and so we define the A sets as complements of the situations covered by the table. Hence, for example, if $getMode(loc_1) = read$ and $getMode(loc_2) = read$ for an entry point loc_1 and an end point loc_2, the set A will be $A = \{read\}$.

Note also that the atomic sections defined using the notion of AI invariants *overlap*, i.e., an end location of a previous atomic section is the entry location of the following atomic section.

4.3 Dynamic Refinement of Atomic Sections

Dynamic analysis can be used to prune the set $Atomic(v)$ obtained from the user or by static analyses such as the ones mentioned above. The idea is to remove from the set the candidate atomic sections (or the branches of such atomic sections) which are not really intended to be executed atomically—similarly as in [16].

Assume that we have a testing oracle which can distinguish between correct and incorrect executions of the application, e.g., based on assertions, checksums, or output analysis. Then we run the application several times and during each run we check which atomic sections, or, more precisely, which branches of atomic sections given by the appropriate entry and exit points, were violated and collect them in a set $ViolatedAtomic(v)$. If a run is classified by the oracle as correct, the set $Atomic(v)$ is changed for each shared variable v as follows: for each pair of entry and exit locations from the set $ViolatedAtomic(v)$, the set A is changed to $A = \{read, write\}$ which causes the algorithm not to warn about atomicity violation in the given part of the code next time. The pruning ends when the set $Atomic(v)$ is not changed for any shared variable v in any run out of a predefined number of consecutive correct executions. Finally, all the entry-exit pairs which were not seen during the pruning process are removed from the set of monitored atomicities by setting their set A to $\{read, write\}$. For covering more execution interleavings, noise injection can be used during the pruning process as well.

After the pruning, the set $Atomic(v)$ often contains atomic sections which AtomRace can never report as violated because all their end points have the set $A = \{read, write\}$. For performance reasons, such atomic sections are, of course, to be completely removed from $Atomic(v)$.

5. SELF-HEALING

Data races and atomicity violations may be corrected manually, but one can also go a step further and try to correct ("heal") them automatically at the runtime. For example, in [13], several techniques for *self-healing* of data races detected using a modification of the Eraser algorithm [25] have been proposed. These techniques are not able to remove a bug from the code but they are able to prevent its manifestation.

The first class of self-healing techniques studied in [13] is based on *affecting the scheduler*. Before executing a problematic part of code, the currently running thread invokes the `Thread.yield()` method, which causes a context switch. Next time, the thread gets an entire time window from the scheduler and so it can pass the problematic code section without an interruption with a much higher probability. This technique can also be used in an opposite way. If some thread t is accessing a shared variable or is executing some atomic section, all other threads can detect this situation and call `Thread.yield()` or `Thread.sleep()` and allow t to finish the problematic piece of code. The scheduler can also be influenced by changing priorities of threads. A thread increases its priority before a problematic part of code and decreases the priority to the original value after the problematic section.

The healing techniques based on influencing the scheduling do not guarantee that a detected problem will really be completely removed, but they can decrease the probability of its manifestation. These techniques do not work well if the section whose atomicity is to be enforced is longer or if the application is running in a true concurrent multi-processor environment. On the other hand, these techniques introduce a reasonable overhead. Moreover, due to the nature of the approach, the healing is safe from the point of view that it does not cause new, perhaps even more serious problems (such as deadlocks).

The second class of self-healing techniques studied in [13] injects *additional healing locks* to the application. Every time a critical variable on which a possibility of a data race was detected is accessed, the accessing thread must first lock a specially introduced lock. Such an approach guarantees that the detected problem cannot manifest anymore. However, introducing a new lock can lead to a deadlock, which can be even more dangerous for the application than the original problem. Moreover, a frequent locking can cause a significant performance drop in some cases.

Actually, the AtomRace algorithm was inspired by the self-healing technique that consists in introducing additional synchronisation to the application. Therefore, self-healing capabilities can be introduced to AtomRace in a straightforward way: the predefined atomic sections can be enclosed by the

use of healing locks, or one can add some code influencing the scheduler at their entry and end points.

5.1 Healing Assurance

As was mentioned before, the use of additional healing locks can reliably heal a detected data race or atomicity violation, but it can cause a deadlock. As a part of our further work on the subject, we are now studying methods how to avoid such a scenario. Let us mention the basic ideas that we are developing as they are related to the AtomRace algorithm. The first idea is to use static analysis and the second one is to use dynamic deadlock detection or prevention mechanisms.

Static analysis can be used for healing assurance as follows. Firstly, atomic sections to be monitored by AtomRace are inferred. Then, one can statically check (in an approximate way) whether there are some synchronisation actions within them. If an atomic section contains a possibility of any kind of synchronisation, it is considered as potentially dangerous for healing via additional locks as their use could lead to a nested synchronisation and hence a possible deadlock. Such atomic sections will therefore preferably *not* be healed using additional synchronisation.

We have implemented a first (intraprocedural) prototype of the above static analysis using FindBugs [11, 2]. It takes a list of atomic sections and checks whether there is no bytecode instruction that can potentially cause a synchronisation in between of an entry and an end location of an atomic section. Currently, `monitorenter`, `invokevirtual`, `invokestatic`, `invokespecial`, and `invokeinterface` are considered as potentially problematic instructions. This is a conservative overapproximation because many methods executed by the invocation instructions will be synchronisation safe. Therefore we are currently working on an implementation of an interprocedural analysis which will compute instructions transitively reachable from a given atomic section via method invocations.

In the case of using *dynamic analysis* for healing assurance, one can proceed in a different way, namely combine data race and atomicity violation healing with a suitable dynamic deadlock detection or prevention mechanism (such as the one recently proposed in [26] and implemented on top of ConTest). In such a case, atomic sections are inferred, and the application is executed and monitored by AtomRace. When some data race or atomicity violation is detected, its healing is started, but at the the same time, a dynamic deadlock detection or prevention mechanism is activated. If the deadlock detection or prevention algorithm detects a deadlock (or a possible deadlock) due to the use of healing locks, it releases the healing locks (or skips locking them).

6. PROTOTYPE IMPLEMENTATION AND EXPERIMENTS

We have implemented data race and atomicity violation detection tool based on AtomRace algorithm. The tool is implemented in Java on top of ConTest [4]—a concurrency testing tool which provides us with a listeners architecture [20], static bytecode instrumentation, and noise injection heuristics [27]. Our static analyses are implemented in FindBugs [11, 2]—a Java bytecode static analysis tool. We have also implemented the architecture covering execution monitoring (done by ConTest) and healing blocks needed for self-healing as they were depicted in Figure 2.

ConTest tool instruments not only accesses to shared variables (fields in Java) and array cells accesses but also synchronization related events, e.g., monitors and threads events, and code coverage related events, e.g., basic blocks and methods entry points, while the AtomRace uses only before and after shared variables and array cells accesses instrumentation points. ConTest provides us at each instrumentation point with most of information needed for analysis but some of them we have to compute on-the-fly, e.g., whether the array cell belongs to shared or local array. Other instrumentation points can be used for placing of our special *atomExitEvent*.

We have also fully implemented all three noise generating heuristics presented in Section 3.3. The difference between our and ConTest injection heuristics is in the place where the noise is placed. ConTest injects noise with the intention to see different access interleavings and/or better synchronization coverage but it cannot take into account the atomic sections used by AtomRace. Our heuristics put the noise directly between $beforeAccessEvent$ and $afterAccessEvent$ and therefore it increases the duration of monitored atomic sections.

We have only partially implemented static analyses for obtaining atomicity as they were presented in the previous section. Currently, we support only load-and-store atomicity pattern for pattern based static analysis and only intraprocedural static analysis for static inferring AI invariants. The interprocedural calls are in our case replaced with *atomExitEvent*s and thus, not checked by the algorithm.

6.1 Data Race Experiments

We have evaluated AtomRace on several examples including small toy example of bank account simulating program with improper synchronization, IBM web crawler algorithm embedded in an IBM product with 19 classes and 1200 lines of code, and Java TIDorb project with 1400+ classes. The Java TIDorb is a CORBA-compliant ORB (Object Request Broker) product that is part of the MORFEO Community Middleware Platform. We have used several tests created by the developers and available in the project repository. In the following, we present the results achieved only for one of them—*echo concurrent* test. It starts the server for handling incoming requests and then starts a client which constructs several client threads (10 in our case) each sending requests (40 in our case) to the server. Results for other tests will be available in [15].

In bank example, AtomRace worked well and the data races were correctly detected. AtomRace also identified data race already known in web crawler in all executions it was seen.

In the case of TIDorbj echo concurrent test, AtomRace detected several exhibitions of data races even during the first execution. After a few executions with a little noise injected by ConTest, AtomRace correctly identified all four variables which are involved in data races. Inspection of the pinpointed pieces of code showed that AtomRace really

	None	CT 50	CT 150	Rand 50/50	Loc 1000/50	Var 500/50	Var 500/150	Var 750/50	Var 1000/50
2 proc.	3,36 / 0,89	45,26 / 2,09	62,12 / 2,36	16,77 / 2,22	0,83 / 0,22	257,46 / 3,42	253,97 / 3,52	362,92 / 3,84	674,35 / 3,34
4 proc.	1,58 / 0,37	31,79 / 1,9	40,87 / 2,42	11,07 / 2,27	11,38 1,71	261,38 / 3,63	271,05 / 3,73	387,91 / 3,82	667,46 / 3,38
8 proc.	2,55 / 0,49	35,47 / 2,31	55,74 / 2,35	10,87 / 2,18	10,74 / 2,07	270,44 / 3,68	268,68 / 3,7	401,00 / 3,88	666,79 / 3,25

Table 2: Noise injection influence on data race detection efficiency

detected true races and did not produce any false alarm. Because the data races were exhibited relatively rarely, it was a good opportunity to study effects of different computers[3] as well as different noise injection strategies as shown in Table 2 for data races.

Table columns contain different noise injection strategies and rows contain different architectures. Values in the table consist of two values *races/coverage*. The *races* value represents the average number of data races detected during the one execution and the *coverage* value represents the average number of distinct variables over which a race has been detected (out of 4). The column labeled with *None* shows how often are races detected without any noise injection heuristics used. In fact, there is already some noise injected by the presence of our code at the instrumented points and this noise can increase the probability of race manifestation rapidly in compare to executions without any instrumentation.

Then, different kinds of noise injection heuristics with different parameters has been used. The *CT x* heuristics represents the *shared variable random noise heuristics* provided by ConTest where x represents the per mile of locations where the noise will be injected (1000 means everywhere, 0 nowhere). As can be seen from the table, introducing even a small percentage of noise can rapidly increase the probability of race detection.

The *Rand x/y* shows the results if our random based heuristics described in Section 3.3 was used. The x value represents the per mile of places where a noise was injected and the y value represents the duration of noise injected (in nanoseconds). It can be seen that our random heuristics is not as successful as these from ConTest.

The *Loc x/y* heuristics represents the location based heuristics described in Section 3.3. The meaning of x and y is the same as in the previous heuristics. We have provided the heuristics with the list of all locations where a race has been previously detected. The results are similar to ConTest heuristics but in this case, only seven distinct location in the code has been influenced, so, the performance degradation was smaller.

Finally, the variable based heuristic labeled with *Var x/y* is listed. This heuristics focused noise on a given set of variables which were those four on which the race has been already detected. It can be seen that noise duration changes have minor influence on the percentage of detected races. In this case, the percentage of race detection increased dramatically and therefore this heuristics is very suitable for forcing race occurrences.

[3]The success of concurrency testing is often highly dependent on the testing environment, therefore, we have run our tests on three different machines: two processors 2xIntel Xeon 1,7GHz, four processors 2xDual Core AMD Opteron 2220, and eight processors 2xQuad Core Intel Xeon 5355.

6.2 Atomicity Violations Experiments

We have also evaluated detection capabilities of AtomRace for atomicity violations. The crucial point for atomicity violation detection is how to identify relevant atomic sections in advance. We have implemented two static analyses to infer correct atomicity, however, our experiments show that both of them have limitations. AI invariant based approach needs to have oracle to classify the executions. This was easy to build it using assertions and checksums for first two examples but Java TIDorb was too complex and we were not able to surely determine if violated AI invariants should or should not be removed from the set of AI invariants.

Pattern based approach worked well for bank account example in which it correctly detected the problematic atomic section corresponding to unprotected line of code. In the case of web crawler, there was none such pattern and therefore the analysis did not find any atomicity there. For TIDorb, it found 155 atomic sections but none of them was related to later discovered problematic variables.

6.3 Self-Healing and Performance

The healing ability of our architecture has been already presented in [13]. AtomRace in comparison with a lockset based algorithm we have used before did not produce any false alarm and therefore the performance degradation caused by the healing actions is lower. The memory and processor consumption of AtomRace is also lower because it does not need to compute and maintain lock set for each shared variable. And finally, reports produced by AtomRace directly pinpoint a variable and at least two program locations in the code and therefore it is easier to check what happened.

Our current implementation does not contain any performance optimization. Due to the ConTest implicitly instruments also final and volatile field accesses, we have to determine them on-the-fly. Similar situation is also with local array cells. Therefore performance overhead generated by our implementation is highly dependent on the frequency of executions of instrumented points. Experiments showed that in the case of Java TIDorb the execution of fully instrumented code with only ConTest activated and without any further noise injection caused 5x longer execution and

ConTest together with AtomRace even 25x longer execution. With bank and crawler examples the overhead was a bit lower.

7. CONCLUSIONS

We have presented a novel algorithm called AtomRace which detects data races and atomicity violations at runtime. The algorithm does not produce any false alarms about data races nor about atomicity violation (in the latter case provided that the algorithm is not instructed to monitor code sections which are not really expected to be atomic). Because AtomRace minimises the amount of work with auxiliary data structures shared among the monitored threads, it is—compared to other existing solutions—faster and more scalable. We have also described that AtomRace can be easily incorporated into a self-healing architecture. In fact, this use of AtomRace, within which all the described features of AtomRace are especially welcome (with the fact that AtomRace may miss data races or atomicity violations being less stressed), was one of the main motivations for its proposal. However, the experiments that we have conducted show that AtomRace combined with suitable noise injection mechanisms, which we have also proposed, can as well be quite successfully used for testing of concurrent software aimed primarily at bug finding.

The first experimental results obtained from a prototype implementation of AtomRace provide us also with a lot of inspiration for future work. First, the atomicity inferring mechanisms need to be improved. Our experiences showed that the AI invariant-based approach requires some number of correctness assertions to be present in the code. These are needed for an efficient dynamic pruning of the set of candidate atomic sets obtained from a static analysis. The pattern-based approach for detecting candidate atomic sections worked well, but our current implementation supports only the load-and-store pattern. For the future, we would like to also implement and test dealing with the test-and-use pattern and investigate some more patterns too. Another weakness of our prototype implementation based on ConTest is the overhead it introduces. We believe that this overhead can be significantly reduced. For instance, we instrument and then handle events from many locations in the code whose monitoring is not really needed (like, e.g., dealing with final variables, local arrays, locations important for various ConTest analyses such as code coverage analysis, etc.). These issues can be tackled by a partial instrumentation already available in ConTest, but not yet used by us. To properly use partial instrumentation, one needs to devise a suitable static analysis to decide which locations must be instrumented. Finally, there is also a space for proposing new noise injection heuristics capable of increasing the probability of race detection without significantly degrading the performance.
